# Context

## Passive Safety Systems Reliability is Hard to Quantify

Advanced reactor designs increasingly rely on passive safety systems - but their small, physics-driven forces make performance sensitive to uncertainty, and there is no industry-standard method to quantify their reliability.

### **Low-Magnitude Driving Forces**

Natural circulation, gravity, and pressure differentials replace pumps and active control - increasing sensitivity to boundary conditions.

### **No Established Data Pool**

Active components draw on decades of operational reliability data. No passive analog exists, so assessment must be design- and scenario-specific.

### **Three Open Challenges**

Uncertainty, parameter dependencies, and non-binary success/failure states all complicate integration into standard PSA models.

# Four Categories of Passivity (IAEA-TECDOC-1752)

Passive components are classified into four categories based on their level of passivity and internal complexity [IAEA TECDOC-1752]:

- A. Fully Static. No signal, no power, no moving parts, no moving fluid.
- B. Moving Fluid Only. No mechanical parts but working fluid moves once activated by thermal-hydraulic conditions.
- C. Moving Mechanical Parts. Internal imbalances (e.g., static or hydrostatic pressure) drive mechanical motion.
- D. Intermediate Zone. Passive execution as above, but without internal intelligence to initiate the process.

Categories B, C, and D rely on physical processes such as natural circulation, pressure-driven flows, or internal mechanical responses.

# Three Open Issues in Passive System Reliability

- Uncertainties
  - Reliability is difficult to quantify due to uncertainty in the thermal-hydraulic phenomena driving the system.
- Dependencies
  - Critical parameters influencing natural driving forces may not be statistically independent - treating them as such may overestimate the reliability.
- Integration
  - Behavior often does not conform to binary success/failure logic, complicating integration into traditional event/fault tree PSA models.

# RMPS Methodology

## RMPS Steps:

- Accident scenario definition
- System characterization
- System modeling and identification of uncertainties
- Uncertainty characterization
- Sensitivity analysis
- Reliability evaluation
  - MC Simulation
  - FORM/SORM
  - Surrogate Models
  - Bayesian Estimation

# Bayesian Estimation

# Demonstrating the Approach: the BWRX-300 ICS

The methodology is applied to the Isolation Condenser System (ICS) of the BWRX-300 small modular reactor - a passive system providing decay heat removal and RPV over-pressure protection.

- Safety Function: Decay heat removal on loss of normal heat sink, and RPV isolation, plus over-pressure protection.
- Redundancy: Three identical loops; success requires only one of three (1-of-3) loops to operate.

# Thermal-Hydraulic Simulations

- A TRACE model of the BWRX-300 was developed to simulate a transient that leads to a reactor trip with ICS actuation.
  - 130 iterations were run (Wilks' method (DAKOTA) for 95% tolerance/99% confidence)
- Acceptance Criteria:
  - RPV pressure remains below 150% of the design pressure, 15.45 MPa.
  - Peak cladding temperature is maintained below 1204 C.

| Parameter                       | Distribution                                                 |
|---------------------------------|--------------------------------------------------------------|
| Gas gap thermal conductivity    | Normal ( $\mu = 1.0$ , $\sigma = 0.102043$ ), scaling factor |
| Fuel thermal conductivity       |                                                              |
| Cladding thermal conductivity   |                                                              |
| Fuel specific heat capacity     |                                                              |
| Cladding specific heat capacity |                                                              |

# Results

| Parameter                 | Normal Dist. Parameters ( $\mu, \sigma$ ) |
|---------------------------|-------------------------------------------|
| Peak system pressure      | (7.8328 MPa, 87.5 kPa)                    |
| Peak cladding temperature | (567.59 K, 0.70 K)                        |

# Quantifying Natural Circulation Failure Probability

- Six model variants (Normal, Log-Normal, and Gamma distributions, each with non-informative and weakly-informative priors) were fit via MCMC
  - In every case, the estimated failure probability was effectively zero.
- The complexity of natural circulation, together with the limited scope of parameters considered, means residual uncertainty in natural circulation cannot be ignored.
- As a result, assigning a probability of exactly zero to natural circulation as a failure mode is not appropriate.
- To account for residual uncertainty a failure probability of  $1.0\text{E-}07$  is therefore adopted.

# Isolation Condenser System Unavailability

| Loops Available | Unavailability, $Q$ |
|-----------------|---------------------|
| CC-3            | 1.62E-07            |
| CC-2            | 2.91E-05            |

- Natural circulation unavailability was integrated into an ICS fault tree as a basic event using **Failure Mode & Effect Analysis (FMEA)** with RiskSpectrum software.
- System unavailability was calculated for case where all three loops are available (CC-3) as well as when only two loops are available (CC-2).
- CC-2 used exclusively for event tree analysis of ICS Line Break initiating event in accompanying PSA.
- All three loops considered identical, except only Loop A contains 'ICS Loop Test or Maintenance' basic event.

# Isolation Condenser System Unavailability

- For ESBWR ICS (broadly equivalent design),  $Q = 2.13\text{E-}03$ .
- ESBWR requires 2 of 4 loops operational for success, vice BWRX-300s 1 of 3.
- Unavailability due to 'Loop test or maintenance' basic event has decreased from  $3.84\text{E-}02$  to  $3.05\text{E-}03$  (NUREG/CR-6928 2020 Update)

| Loops Available | Unavailability, $Q$ |
|-----------------|---------------------|
| CC-3            | $1.62\text{E-}07$   |
| CC-2            | $2.91\text{E-}05$   |

|      | Cutset                                                                                                           | Contribution (%) |
|------|------------------------------------------------------------------------------------------------------------------|------------------|
| CC-3 | Common cause failure of all heat exchangers                                                                      | 34.75            |
|      | Spurious isolation of all loops due to isolation valve signal failure                                            | 34.56            |
|      | Spurious isolation of two loops due to isolation valve signal failure with remaining loop in test or maintenance | 26.08            |

|      |                                                                                                               |       |
|------|---------------------------------------------------------------------------------------------------------------|-------|
| CC-2 | Spurious isolation of both loops due to isolation valve signal failure                                        | 54.88 |
|      | Spurious isolation of a loop due to isolation valve signal failure with remaining loop in test or maintenance | 41.88 |

CC-3: Three loops available

CC-2: Two loops available

# Core Damage Frequency Analysis

- Level 1 PSA performed, involving analysis of initiating events, event tree analysis, and FMEA of safety systems
- Credit only taken for passive safety features (no human action, no connection to electrical grid)
- Final Result:** CDF =  $1.23\text{E-}07 \text{ yr}^{-1}$
- Simplified sensitivity analysis shows that a 100-fold increase of natural circulation failure probability increases CDF by only 0.41%

| Initiating Event | Component Failures                                                                                        | Frequency (yr <sup>-1</sup> ) | Contribution (%) | # of Cutsets |
|------------------|-----------------------------------------------------------------------------------------------------------|-------------------------------|------------------|--------------|
| Transient        | CCF of All ICS HXs                                                                                        | 4.23E-08                      | 34.45            | 1            |
| Transient        | Spurious isolation of all ICS loops due to isolation valve signal failure                                 | 4.17E-08                      | 33.98            | 64           |
| Transient        | Spurious isolation of 2 ICS loops due to signal failure, remaining ICS loop in test or maintenance        | 3.18E-08                      | 25.92            | 16           |
| Transient        | CCF of HXs in 2 ICS loops, remaining ICS loop in test or maintenance                                      | 7.16E-10                      | 0.58             | 4            |
| Transient        | CCF of HXs in 2 ICS loops, spurious isolation of remaining ICS loop due to isolation valve signal failure | 4.70E-10                      | 0.38             | 8            |
| Transient        | ATWS with BIS check valve failure                                                                         | 2.60E-10                      | 0.21             | 2            |
| LOCA             | Mechanical failure of RPVIVs                                                                              | 1.68E-10                      | 0.14             | 2            |
| Transient        | ATWS with spurious closure of BIS AOVs                                                                    | 1.21E-10                      | 0.10             | 2            |
| RPVR             | Vessel rupture                                                                                            | 1.00E-10                      | 0.08             | 1            |

# Conclusions

## Key Findings

- **RMPS** successfully quantified the reliability of the passive Isolation Condenser System and enabled its integration into a **Level-1 PSA**.
- The **BWRX-300 ICS** demonstrated robust passive performance, with a conservative natural circulation failure probability of  $1.0 \times 10^{-7}$ .
- **TRACE constitutive correlation uncertainties** had only a marginal impact on ICS performance, and overall plant risk was weakly sensitive to passive natural circulation uncertainty.
- The proposed methodology provides a practical framework for reliability assessment of **future SMRs and advanced passive reactor designs**.

## Lessons Learned

- Numerical stability remains challenging for simulations involving **large naturally convecting volumes**, wide uncertainty ranges, and long transient analyses.
- Accurate **heat transfer boundary conditions** are critical for predicting the transition between short- and long-term passive cooling performance.
